A margin is a statistic based on a ?tted model in which some of or all the. margins— Marginal means, predictive margins, and marginal effects 9. covariates are ?xed. Marginal effects are changes in the response for change in a covariate, which can be reported as a derivative, elasticity, or semielasticity.

The default is to estimate margins for all outcomes. outcomes is a list of one or more outcomes, which are the values of the alternatives variable; see

Stata's margins includes options to control whether the standard errors reflect just the sampling variation of the estimated coefficients or whether they also reflect the sampling variation of the estimation sample.

Margins are statistics calculated from predictions of a previously ?t model at ?xed values of some covariates and averaging or otherwise integrating over the remaining covariates. The margins command estimates margins of responses for speci?ed values of covariates and presents the results as a table.

The ?rst margin, 0.13, is the average probability of a positive outcome, treating everyone as if they were male. The second margin, 0.19, is the average probability of a positive outcome, treating everyone as if they were female. We can compare females with males by rerunning margins and adding a contrast operator:

The margins command can very easily tell you the mean effect: margins, dydx(weight) What margins does here is take the numerical derivative of the expected price with respect to weight for each car, and then calculates the mean. In doing so, margins looks at the actual data. Thus it considers the effect of changing the Honda Civic's weight from 1,760 pounds as well as changing the Lincoln Continental's from 4,840 (the weight squared term is more important with the latter than the former).

the margins and the x axis represents one or more factors or continuous covariates. Specifying horizontal swaps the axes so that the x axis represents the estimates of the margins.

Using Margins for Predicted Probabilities. The margins command (introduced in Stata 11) is very versatile with numerous options. This page provides information on using the margins command to obtain predicted probabilities. Let's get some data and run either a logit model or a probit model. It doesn't really matter since we can use the same margins commands for either type of model.

*Using Margins for Predicted Probabilities*

marginscomputes so-called margins of responses. IA \margin" is a statistic computed from predictions from a model while manipulating the values of the covariates. F\conditional margin": a prediction from a model where all covariates are set to xed values. F\predictive margin": if some covariates are not xed.

This margins syntax with the asbalanced option yields the "least-squares cell means" (SAS terminology), also known as the "estimated marginal cell means" (SPSS terminology), but more generally known as the adjusted cell means. And, because we used the post option, we can use the test command to compare differences in adjusted cell means.

We will use the margins command to get the predicted probabilities for 11 values of s from 20 to 70 for both f equal zero and f equal one. The syntax 20(5)70 means estimate predicted values for y when s equals 20, 25, 30 ... 70. The vsquish option just reduces the number of blank lines in the output.

Stata 11 introduced new tools for making such calculations—factor variables and the margins command. These can do most of the things that were previously done by Stata's own adjust and mfx commands, and much more. Unfortunately, the complexity of the margins syntax, the daunting 50-page reference manual entry that describes it,

Stata's margins command is incredibly robust. It works with nearly any kind of statistical model and estimation procedure, including OLS, generalized linear models, panel regression models, and so forth. It also represents a significant improvement over Stata's previous marginal effects command - mfx - which was subject to various well-known bugs.
